

Suggested Answers to Carboxylic Acid & Derivatives Tutorial

1(a) Decreasing acid strength:

The acidity of a compound depends on the relative stability of its conjugate base anion (A^-). The more stable the conjugate base, the more acidic the compound will be.

In the ethanoate ion (CH_3CO_2^-), the negative charge on oxygen is dispersed over the two highly electronegative oxygen atoms resulting in two equivalent resonance structures. Hence, CH_3CO_2^- ion is resonance-stabilised to a larger extent than $\text{C}_6\text{H}_5\text{O}^-$ ion.

In the phenoxide ion ($\text{C}_6\text{H}_5\text{O}^-$), the p-orbital containing the lone pair of electrons on the O atom overlaps with the π -electron cloud of the benzene ring so that the negative charge on O delocalises into the benzene ring. The dispersal of negative charge stabilises $\text{C}_6\text{H}_5\text{O}^-$ ion but this resonance stabilisation is not as great as that in the CH_3CO_2^- ion.

In the ethoxide ion ($\text{CH}_3\text{CH}_2\text{O}^-$), the electron-donating alkyl (ethyl) group intensifies the negative charge on O atom, which destabilises $\text{CH}_3\text{CH}_2\text{O}^-$ ion. Therefore, $\text{CH}_3\text{CH}_2\text{O}^-$ is the least stable.

(b) Decreasing acid strength:

The acidity of a compound depends on the relative stability of its conjugate base anion (A^-). The more stable the conjugate base, the more acidic the compound will be.

Compared to CH_3COO^- ion, the CF_3COO^- , CCl_3COO^- and $\text{C}/\text{CH}_2\text{COO}^-$ ions are more stable due to the presence of electron-withdrawing F or Cl group(s) to disperse the negative charge and hence stabilising the anion.

CCl_3COO^- ion is more stable than $\text{C}/\text{CH}_2\text{COO}^-$ ion as it has 2 more electron-withdrawing Cl groups to disperse the negative charge.

Since F is more electronegative than Cl, the F group is more electron-withdrawing than the Cl group and the negative charge is dispersed to a greater extent in CF_3COO^- ion than in CCl_3COO^- ion. Hence CF_3COO^- ion is more stable than CCl_3COO^- ion.

2 Decreasing ease of hydrolysis:

The carbon of the acyl group in $\text{C}_6\text{H}_5\text{COC}/$ has a higher δ^+ charge (or is more electron deficient) as it is bonded to two electronegative atoms (O and Cl). The carbon bonded to the chlorine atom in $\text{C}_6\text{H}_5\text{CH}_2\text{C}/$ has lower δ^+ charge (or is less electron deficient) as it is bonded to only one electronegative atom (Cl). Hence, $\text{C}_6\text{H}_5\text{COC}/$ can attract nucleophiles more easily and is more susceptible to nucleophilic attack as compared to $\text{C}_6\text{H}_5\text{CH}_2\text{C}/$.

In addition, the carbon of the acyl group in $\text{C}_6\text{H}_5\text{COC}/$, being sp^2 hybridised and trigonal planar, provides less steric hindrance during nucleophilic attack compared to the carbon bonded to the chlorine atom in $\text{C}_6\text{H}_5\text{CH}_2\text{C}/$, which is sp^3 hybridised and tetrahedral. Thus, $\text{C}_6\text{H}_5\text{COC}/$ undergoes hydrolysis with ease with water (a weak nucleophile) while $\text{C}_6\text{H}_5\text{CH}_2\text{C}/$ requires a stronger nucleophile OH^- under heating.

$C_6H_5C/$ is the least susceptible to hydrolysis. This is because the p orbital containing the lone pair of electrons on the C/ atom overlaps with the π electron cloud of the benzene ring, resulting in a lone pair of electrons in the p orbital of C/ delocalising into the benzene ring. As a result, the C-C/ bond has partial double bond character. Since the bond is strengthened, the cleavage of this bond (which is necessary during hydrolysis) is made very difficult.

3 (a) Test: Add aq Na_2CO_3 (or aq $NaHCO_3$) to each compound in a test-tube.

Observation: For C_6H_5COOH : Effervescence observed, CO_2 gas evolved
formed white ppt with limewater/aq $Ca(OH)_2$.
For C_6H_5OH : No effervescence / no gas is evolved.

Other tests: Neutral $FeCl_3(aq)$: Violet complex observed for phenol. No violet complex for benzoic acid.
Or aqueous Br_2 : Phenol decolourises orange Br_2 and a white ppt is formed. No decolourisation of Br_2 and no white ppt for benzoic acid.

(b) Test: Add aq $AgNO_3$ to each compound in a test-tube.

Observation: For $CH_3CH_2COC/$: White ppt ($AgC/$) formed and white fumes ($HC/$) evolved.
For C/CH_2CH_2COOH : No white ppt and no white fumes.

Note: Aq. Na_2CO_3 should not be used as a distinguishing test between acid chlorides and carboxylic acids. Acid chlorides such as $CH_3CH_2COC/$ undergo hydrolysis readily in aqueous medium, under room temperature conditions. The products, $HC/$ and carboxylic acid, will react with aq. Na_2CO_3 to produce CO_2 .

(c) Test: Add $NaOH(aq)$ to each compound in a test-tube and heat in a hot water bath. Then add aq I_2 .
OR Add $NaOH(aq)$ and $I_2(aq)$ to each compound in a test-tube and heat in a hot water bath.

Observation: For $CH_3COOCH(CH_3)_2$: Yellow ppt of CHI_3
For $CH_3COOCH_2CH_2CH_3$: No yellow ppt formed.

- (d) Test: Add 2 drops of aq KMnO_4 and aq H_2SO_4 to each compound in a test-tube and heat in a hot water bath.

Observation: For HCOOH : Purple KMnO_4 decolourises. Effervescence observed, CO_2 gas evolved formed white ppt with aq limewater/ $\text{Ca}(\text{OH})_2$.

For CH_3COOH : Purple KMnO_4 is not decolourised.

Note: HCOOH also gives a positive test with Tollens' reagent & Fehling's solution.

Note: HCl with ZnCl_2 can also be used for the first step.

- 6 (a)

Evidence	Deduction
F, $\text{C}_8\text{H}_8\text{O}_2$	F has a high C:H ratio of 1:1 and > 6 C atoms → F likely contains benzene ring
F insoluble in water	→ presence of large non-polar group such as benzene ring in F
F dissolves in $\text{NaOH}(\text{aq})$	F undergoes <u>acid-base</u> reaction → F contains <u>acidic</u> functional group → F is either a <u>phenol</u> or a <u>carboxylic acid</u>
F reacts with 2,4-DNPH	F undergoes <u>condensation</u> with 2,4-DNPH → F is a <u>carbonyl compound</u>

F does not react with Fehling's solution	F is <u>not oxidised</u> by Fehling's solution → F is <u>not</u> an aliphatic aldehyde → F is either an <u>aromatic aldehyde</u> or a <u>ketone</u>
F + Br ₂ (aq) → G (C ₈ H ₅ O ₂ Br ₃)	F undergoes <u>electrophilic substitution</u> with Br ₂ (aq) → F contains a <u>strongly activated</u> benzene ring → F is a <u>phenol</u>
G has 3 H atoms substituted with 3 Br atoms	→ G has <u>Br</u> substituted at the <u>2,4 and 6</u> positions with respect to the phenol OH group.
F + I ₂ / OH ⁻ (aq) then H ⁺ → H	F undergoes oxidation by alkaline I ₂ (aq) (positive iodoform test) followed by acid-base reaction to form H → F is a <u>methyl ketone</u> → H is a <u>carboxylic acid</u> with 1 C less than F
H dissolves in both NaOH(aq) and Na ₂ CO ₃ (aq).	H undergoes <u>acid-base</u> reaction with NaOH and Na ₂ CO ₃ → H is a <u>carboxylic acid (confirmed)</u>

Note: An extra mol of OH⁻ is required to neutralise the acidic phenol group.

7

Ans: **B (2)**

In D₂O solvent, the phenol and COOH groups can lose H⁺ to form the respective conjugate bases.

Using the COOH group as an example:

The carboxylate anion can then undergo basic hydrolysis with D₂O to form RCOOD as the deuterated solvent is present in large excess:

8(a)

Step 1: HCN, trace of KCN

Step 2: ethanolic KCN, heat/heat under reflux

Step 3: dilute HCl, heat/heat under reflux

[Note : Step 1 and 2 involving cyanide could be carried out in any order]

(b) (i) cis-trans isomerism

(ii) excess concentrated H₂SO₄, heat (or Al₂O₃, heat)

(iii) The pK_a values suggest that **K**, having a low first pK_a coupled with a high second pK_a produces the more stable mono-anion.

The first pK_a is much lower implying that **K** loses its first proton more readily to form the mono-anion and it is therefore also more difficult for the mono-anion of **K** to accept H⁺. The second pK_a is much higher, implying it is more difficult for the mono-anion to lose a 2nd proton, thus mono-anion of **K** more stable.

(iv) The more stable anion is produced from the cis isomer (**K**) as intramolecular hydrogen bonding can exist (shown below) as the oxygen with the negative charge is in close proximity to the H atom of the adjacent COOH group.

Note:

pK_a (1) of the cis isomer, **K**, should be smaller since the mono-anion is more stable and less likely to accept back H^+ as compared to the trans isomer.

pK_a (2) of the cis isomer, **K**, is larger as it is now more difficult to lose the 2nd proton as it is involved in intramolecular hydrogen bonding.)

(c) **L** is

Evidence	Deductions
J or K $\rightarrow$ L , $C_4H_2O_3$	J/K ($C_4H_4O_4$) loses a water molecule to form L ($C_4H_2O_3$) L could be
L , $C_4H_2O_3$ is neutral.	L is not a carboxylic acid since it is neutral.
L has no reaction with Na.	L does not undergo redox with Na. $\rightarrow$ L has no $-OH$ group.
L has no reaction with 2,4-DNPH.	L does not undergo condensation with 2,4-DNPH. $\rightarrow$ L is not an aldehyde or ketone. L is formed from the condensation reaction between $-H$ of one $COOH$ group and $-OH$ of another $COOH$ group, thus losing one molecule of water. The 2- $COOH$ groups must be in close proximity $\rightarrow$ hence the isomer is K , cis isomer.

(d)

Gas Q could be CO_2 .

Evidence	Deductions
Malic acid, $C_4H_6O_5$ on heating with $K_2Cr_2O_7$ forms N .	<u>oxidation</u> of 2° alcohol to ketone with loss of 2H atoms. → N is a ketone with molecular formula $C_4H_4O_5$
Heating N produces P , $C_3H_4O_3$ and gas Q .	Gas Q could be CO_2 as difference in molecular formula of N and P is CO_2 .
N and P react with 2,4-DNPH.	N and P undergo <u>condensation</u> reaction with 2,4-DNPH → N and P are carbonyl compounds
P gives yellow ppt with aqueous alkaline iodine.	P undergoes <u>oxidation</u> with aqueous alkaline I_2 (positive iodoform test) → P has $-COCH_3$ group. CHI_3 is the yellow ppt.
